Abstract

Autoimmune diseases are characterized by tissue damage and loss of function due to an immune response that is directed against specific organs. This review is focused on celiac disease (CD), an autoimmune enteropathy, and type 1 diabetes (T1D), a hyperglycemia caused by a destructive autoimmune process targeting the insulin-producing pancreatic islet cells. Even if environmental factors and genetic susceptibility are clearly involved in the pathogenesis of autoimmunity, for most autoimmune disorders there is no or little knowledge about the causing agent or genetic makeup underlying the disease. In this respect, CD represents a unique autoimmune disorder because a close genetic association with HLA-DQ2 or HLA-DQ8 haplotypes and, more importantly, the environmental trigger (the gliadin fraction of gluten-containing grains wheat, barley, and rye) are known. Conversely, the trigger for autoimmune destruction of pancreatic \( \beta \) cells in T1D is unclear. Interestingly, recent data suggest that gliadin is also involved in the pathogenesis of T1D. There is growing evidence that increased intestinal permeability plays a pathogenic role in various autoimmune diseases including CD and T1D. Therefore, we hypothesize that besides genetic and environmental factors, loss of intestinal barrier function is necessary to develop autoimmunity. In this review, each of these components will be briefly reviewed.

Keywords

tight junctions; intestinal permeability; zonulin; celiac disease; type 1 diabetes; gliadin

Introduction

It is generally accepted that the interplay between environmental factors and specific susceptibility genes underlies the aberrant immune response responsible for the onset of autoimmune diseases. Fewer than 10\% of those individuals with an increased genetic susceptibility actually develop clinical disease. This suggests a strong environmental trigger in the preautoimmune process. Environmental factors are also likely to affect the outcome of the process and the rate of progression to disease in those individuals who develop...
autoimmunity. One of the current theories is that intestinal luminal antigens absorbed through the gut may be involved. The intestinal epithelium is the largest mucosal surface and provides an interface between the external environment and the mammalian host. Healthy, mature gut mucosa with their intact tight junctions (TJ) serve as the main barrier to the passage of macromolecules (Fig. 1). In a physiological state, quantitatively small but immunologically active antigens may cross the mucosal barrier. These antigens are absorbed across the mucosa via two functional pathways. The vast majority of absorbed proteins (up to 90%) cross the intestinal barrier through the transcellular pathway followed by lysosomal degradation that converts the proteins into smaller, nonimmunogenic peptides. The remaining portion of proteins is transported as intact proteins, resulting in antigen-specific immune responses. This latter phenomenon utilizes the Microfold (M) cell pathway or the paracellular pathway, which involves a subtle but sophisticated regulation of intercellular TJ that leads to antigenic tolerance.1-2 When the integrity of the gut barrier is compromised (TJ disassembly), as is seen during prematurity or exposure to radiation, chemotherapy and/or toxins, an immune response to environmental antigens that crossed the gut mucosa may develop, leading to autoimmune diseases or food allergies.2-3 The cells that play a key role in this immune response lie in close proximity to the intestinal epithelial barrier.4-5 Another critical factor for intestinal immunological responsiveness is the human leukocyte antigen (HLA) system. HLA class I and II genes encode antigen presenting cell (APC) glycoprotein receptors that present antigens to T cells in the intestinal mucosa.6-8 Susceptibility to at least 50 diseases, including celiac disease (CD) and type 1 diabetes (T1D), has been associated with specific HLA class I or class II alleles. A common denominator of these diseases is the presence of several preexisting conditions that lead to an autoimmune process. The first is a genetic susceptibility for the host immune system to recognize, and potentially misinterpret, an environmental antigen presented within the gastrointestinal tract. Second, the host must be exposed to the antigen. Finally, the antigen must be presented to the gastrointestinal mucosal immune system following its M-cell passage or paracellular passage (normally prevented by TJ competency) from the intestinal lumen to access the gut submucosa.2-3,9-11 In all cases, increased permeability precedes disease and causes an abnormality in antigen delivery that triggers immune events, eventually leading to a multiorgan process and autoimmunity.1 We therefore hypothesize that genes, environment, and loss of intestinal barrier function are all necessary to develop autoimmunity, especially CD and T1D.

Genetic Component of Autoimmunity

Celiac Disease

The complex interplay between genetic and environmental factors leading to the lack (or loss) of gluten tolerance is still poorly understood. Prevalence studies performed in Europe12 and our recent data generated in the U.S.A.13 both demonstrate a higher prevalence of CD among asymptomatic first-degree relatives of CD patients than among the general population. Of 24 reported pairs of identical twins with CD, 75% were concordant for disease.14 Nonetheless, it appears that there are instances of discordance for CD among monozygotic twins. If it is assumed that twins ingest similar dietary grains, such discordance suggests the importance of environmental factors in disease expression. Class II HLA genotypes DQ2 and DQ8 play a major predisposing role, being found in almost 100% of patients. HLA class II genes are highly polymorphic, with the majority of polymorphisms encoding the regions of the molecule that constitute the sides and floor of the peptide binding groove. Different combinations of HLA-DQ haplotypes influence the risk of disease, which is much higher in subjects showing a double copy of the DQB * 02 genes (DQ2/DQ2 and DQ2/DR7) than the DQ8 (DR4)/X genotype.15-16 Inheritance of specific HLA-DQ genotypes explains 40% of the genetic predisposition to CD, while the remaining 60% is related to a complex, still-undefined mosaic of non-HLA genes, each of which adds a small contribution to the risk of CD development.
For instance, recent reports have described non-HLA genes encoding for proteins involved in the regulation of intestinal permeability to be associated with susceptibility for CD. Polymorphisms in the MYO9B gene were shown to be associated with increased susceptibility for gluten-sensitive enteropathy (GSE) in a Dutch cohort of GSE patients, and more recently, the TJ-related genes PARD3 and MAGI2 were also shown to be genetically associated with CD.

**Type 1 Diabetes**

The first diabetes susceptibility genes to be identified were the HLA genes, located on chromosome 6p21. Subsequent studies demonstrated an association between the disease and the insulin gene region on chromosome 11p. In the mid- to late 1990s, high throughput screening of the entire human genome in families with two or more affected siblings was used to identify additional chromosomal regions that may contain susceptibility genes for T1D. Over 20 loci showed evidence for linkage with the disease in different data sets. All of the studies consistently reported linkage to the HLA gene region (designated IDDM1). Several genome screens, in combination with family-based association studies, also supported a role for the insulin gene region (designated IDDM2) in disease susceptibility. Linkage to eight additional loci was replicated in independent data sets: IDDM4 (chromosome 11q13), IDDM5 (chromosome 6q25), IDDM7 (chromosome 2q31), IDDM8 (chromosome 6q27), IDDM10 (chromosome 10p11–q11), IDDM12 (chromosome 2q33), IDDM13 (chromosome 2q35), and IDDM15 (chromosome 6q21). In addition, the locus-designated IDDM6 (chromosome 18q21) showed consistent evidence for association with the disease in family studies. Although the chromosomal locations of these loci are known, the precise identity of the susceptibility genes in these regions remains to be determined. The genome screens confirmed that, as for CD, the HLA gene region (IDDM1 locus) is the major genetic determinant of disease risk, accounting for 42% of the familial inheritance of T1D. The IDDM2 locus (the insulin gene region) contributes an additional 10% of genetic susceptibility.

Interestingly, also polymorphisms in the MYO9B gene were shown to be associated with susceptibility for T1D. This observation indicates that the susceptibility for the development of both CD and T1D is related to genes involved with intestinal permeability.

The role of the intestinal barrier in the development of CD and T1D will be discussed below.

**Gliadin as an Environmental Component of Autoimmunity**

**Celiac Disease**

Gliadin is the environmental factor that triggers CD. It is the gliadin fraction of wheat gluten and similar alcohol-soluble proteins in other grains (collectively known as prolamins) that are associated with the development of intestinal damage. A common feature of the prolamins of wheat, rye, and barley is a high content of glutamine (>30%) and proline (>15%), whereas the nontoxic prolamins of rice and corn have lower glutamine and proline content. However, the environmental component influencing CD development is complex and still unclear. Some aspects of gluten intake may influence the risk of CD occurrence, particularly (1) the amount of ingested gluten (the higher the amount, the higher the risk); (2) the quality of ingested gluten (some grains contain more toxic epitopes than others); and (3) the pattern/timing of infant feeding. Recent studies suggest that the pattern of infant nutrition may have a critical role on the development of CD and other autoimmune disorders. Breastfeeding is thought to delay or reduce the risk of developing CD. The positive effects of breast milk can be attributed, at least in part, to its influence on the microbial colonization process of the newborn intestine. The genus *Bifidobacterium* is predominant in feces of breast-fed infants, while a larger variety of bacterial groups (*Bacteroides*, *Streptococcus*, *Clostridium*, etc.) integrate the fecal community.
microbiota of formula-fed infants. Changes in the composition of the intestinal microbiota also occur as a consequence of the subsequent shifts from breastfeeding or formula feeding to weaning and the introduction of solid food. Alterations in the intestinal balance between beneficial and potentially harmful bacteria have also been associated with allergy, type 1 diabetes, and inflammatory bowel diseases.

**Type 1 Diabetes**

It is believed that genetically predisposed individuals develop T1D after encountering one or more environmental triggers of the disease. Rapid advances could be made in disease prevention and treatment if these environmental triggers were identified. Among others, gliadin has recently been the object of a series of studies that aim at establishing its role in the pathogenesis of T1D. Early introduction of gliadin-containing cereals was recently reported to increase the risk of islet cell autoimmunity in humans. Gliadin-specific, lamina propria-derived T cells play an important role in the pathogenesis of CD. The same HLA class II haplotype, DQ (α 1 * 0501, β1 * 0201), that is associated with gliadin peptides in CD is also one of two HLA class II haplotypes inherited most frequently by people with T1D. There is also evidence of immunological activity in the small intestine of T1D patients: jejunal specimens from T1D patients have been found to contain significantly greater concentrations of interferon gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α) positive cells than those of healthy controls, suggesting an inflammatory response.

Findings from studies using non obese diabetic (NOD) mice and the BioBreeding diabetes-prone (BBDP) rats have implicated wheat gliadin as a dietary diabetogen. In BBDP rats, gliadin exposure is accompanied by increased intestinal permeability, and changes in gut microflora composition (unpublished data) presumably allow food antigens to come in contact with the underlying lamina propria. Feeding NOD mice and BBDP rats a gluten-free hydrolysed casein diet resulted in a delay and reduction of T1D development. Interestingly, these animal models of T1D also showed that the moment of exposure to wheat proteins is important for the development of T1D. Delaying the exposure to diabetogenic wheat proteins by prolonging the breastfeeding period reduced T1D development in the BBDP rats. Furthermore, exposing neonatal rats or mice to diabetogenic wheat components or bacterial antigens reduced T1D incidence, which is probably due to the induction of immunological tolerance.

Rats that were fed wheat protein–based diets develop T1D and display a mild celiac-like enteropathy. Mesenteric lymph nodes (MLNs), which drain the gut, are the major inductive site where dietary antigens are recognized in the gut-associated lymphoid tissue. The authors described an increase in the expression ratio of T-bet:Gata3, master transcription factors for Th1 and Th2 cytokines, respectively, in the MLN from wheat-fed BBDP rats compared with
that from BBDR rats, mainly due to decreased Gata3 expression.\textsuperscript{34} CD3\textsuperscript{+}CD4\textsuperscript{+}IFN\textgamma\textsuperscript{+} T cells were more prevalent in the MLN of wheat-fed BBDP rats, but remained at control levels in BBDP rats fed a diabetes-retardant wheat-free diet. BBDP MLN cells proliferated in response to wheat protein antigens in a specific, dose-dependent manner, and >93\% of cells were CD3\textsuperscript{+}CD4\textsuperscript{+} T cells. This proliferation was associated with a low proportion of CD4\textsuperscript{+}CD25\textsuperscript{+} T cells and a high proportion of dendritic cells in the MLN of BBDP rats.\textsuperscript{34} These results suggest that, before insulitis is established, the MLNs of wheat-fed BBDP rats contain an unusually high proportion of Th1 cells that proliferate specifically in response to wheat protein antigens. Collectively, these studies suggest a deranged mucosal immune response to gliadin in T1D and a direct link between gliadin-induced activation of gut mucosal T cells and insult of pancreatic islet cells (Fig. 2).

**Intestinal Barrier Component of Autoimmunity**

**The Zonulin System**

In recent years, much has been discovered about the structure, function and regulation of TJ (Fig. 1). However, the precise mechanism(s) by which they operate is still not completely understood. The discovery of zonula occludens toxin (Zot), an enterotoxin elaborated by \textit{Vibrio cholerae} that reversibly opens the TJ, increased our understanding of the intricate mechanisms that regulate the intestinal epithelial paracellular pathway. Zot action is mediated through a cascade of intracellular events that lead to PKC\textalpha-dependent polymerization of actin microfilaments that are strategically localized to regulate the paracellular pathway.\textsuperscript{43} By using immunofluorescence binding studies, we found that Zot binding varies within the intestine, and is detectable in the jejunum and distal ileum, but not in the colon, and decreases along the villous-crypt axis.\textsuperscript{44} This binding distribution coincides with the differential intestinal epithelial paracellular permeability along the villous axis\textsuperscript{45} and with the regional effect of Zot on intestinal permeability\textsuperscript{44} and on F-actin redistribution in the mature cells of the villi.\textsuperscript{43,46} These combined data demonstrate that Zot regulates the TJ in a rapid, reversible, and reproducible fashion. Based on this observation, we postulated that Zot may mimic the effect of a functionally and immunologically related, physiologically relevant endogenous modulator of epithelial TJs. By using affinity-purified anti-Zot antibodies and the Ussing chamber assay, we were able to identify a human intestinal Zot homolog that we designated as zonulin.\textsuperscript{47} Affinity-purified zonulin reduced transepithelial electrical resistance (TEER) compared to the media control in both monkey jejunum (35.3\% decrement) and ileum (25.6\% decrement), but not in the colon.\textsuperscript{47} \textit{V. cholerae}–derived Zot and human zonulin both act on intestinal TJs\textsuperscript{43,44,47–49} (Fig. 3) and display the same regional activity\textsuperscript{44} coincident with Zot receptor distribution in the intestine,\textsuperscript{43,44} suggesting that these two molecules interact with the same receptor. We compared the primary amino acid structures of Zot and zonulin to provide insights into the structural requirements for ligand engagement of the receptor coupled to intestinal TJ regulation. The NH\textsubscript{2}-termini of zonulin and the Zot active fragment share a common octapeptide motif (GGVLRQPG) that is critical for intestinal receptor binding.\textsuperscript{47–50} The synthetic octapeptide motif, named AT1001, has since been demonstrated to be an efficient inhibitor of both Zot and zonulin.\textsuperscript{47–50} The physiological role(s) of the zonulin system remains to be established. This pathway appears to be involved in several functions, including TJ regulation responsible for the movement of fluid, macromolecules and leukocytes between the bloodstream and the intestinal lumen and vice versa. Another possible physiological role of intestinal zonulin is the protection against microorganism colonization of the proximal intestine (innate immunity).\textsuperscript{51}

**Zonulin and Autoimmune Diseases**

Intestinal TJ dysfunction occurs in a variety of clinical conditions, including food allergies, infections of the gastrointestinal tract, autoimmune diseases, and inflammatory bowel diseases.
Several autoimmune diseases are characterized by loss of intestinal barrier function. To explore the possibility that zonulin is involved in the pathogenesis of these diseases, we focused our studies on CD and T1D, two autoimmune conditions in which the finely tuned regulation of intestinal TJ permeability is lost. To determine whether zonulin production is perturbed during the acute phase of CD, intestinal tissues from patients with active CD and non-CD controls were probed for zonulin expression. Quantitative immunoblotting of intestinal tissue lysates from active CD patients confirmed the increase in zonulin protein compared to control tissues. The zonulin upregulation during the acute phase of CD was confirmed by measuring zonulin concentration in sera of 189 CD patients using a sandwich ELISA. Compared to healthy controls, CD subjects showed significantly higher zonulin serum concentrations \( P < 0.000001 \) during the acute phase of the disease that decreased following a gluten-free diet. Similar results were obtained from T1D subjects. In the BBDP rat model of T1D, we reported that zonulin-dependent increases in intestinal permeability precede the onset of T1D by 2–3 weeks. Oral administration of the zonulin inhibitor AT1001 to BBDP rats blocked autoantibody formation and zonulin-mediated intestinal permeability increase, reducing the incidence of diabetes. Moreover, feeding BBDP rats a gluten-free diet reduced the serum zonulin levels (Visser et al., unpublished results) (Fig. 2). Taken together, these studies suggest that the zonulin-dependent loss of intestinal barrier function is one of the initial steps in the pathogenesis of T1D in the BBDP animal model of the disease.

The involvement of zonulin in T1D pathogenesis was corroborated by our studies in humans, showing that a large subgroup of T1D patients has high serum zonulin levels that correlated with increased intestinal permeability and changes in claudin-1, claudin-2, and myosin IXB genes expression. Moreover, we also provided preliminary evidence suggesting that, like in the BBDP rat model of the disease, zonulin upregulation precedes the diagnosis of the disease in T1D patients.

Link between Gliadin, Zonulin, and Increased Intestinal Permeability in Autoimmunity

Our group has generated evidence that gliadin induces increased intestinal permeability by releasing preformed zonulin. Intestinal cell lines exposed to gliadin released zonulin in the cell medium with subsequent zonulin binding to the cell surface, rearrangement of the cell cytoskeleton, loss of occludin-ZO1 protein–protein interaction, and increased monolayer permeability. Pre-treatment with the zonulin antagonist AT1001 blocked these changes without affecting zonulin release. When exposed to luminal gliadin, intestinal biopsies from celiac patients in remission expressed a sustained luminal zonulin release and increase in intestinal permeability. Conversely, biopsies from non-CD patients demonstrated a limited, transient zonulin release, which was paralleled by a reduction in intestinal permeability that never reached the level of permeability seen in CD tissues. Interestingly, when gliadin was added to the basolateral side of either cell lines or intestinal biopsies, no zonulin release was detected. The latter finding suggests that gliadin interacts with an intestinal luminal receptor and prompted us to identify this moiety. In vitro experiments showed specific colocalization of gliadin with the chemokine receptor CXCR3 expressed in human and mouse intestinal epithelium and lamina propria. Gliadin exposure led to a physical association of CXCR3 and MyD88. Ex vivo experiments revealed that gliadin exposure to intestinal segments from wild-type mice increased zonulin release and intestinal permeability, while CXCR3−/− intestinal segments failed to respond to gliadin. The increased intestinal permeability appeared to be a specific effect of gliadin, since another CXCR3 ligand, IP-10, did not affect intestinal barrier function. Based on these data, we postulate that gliadin binds to CXCR3 and leads to activation of the zonulin pathway and increased intestinal permeability in a MyD88-dependent fashion.
Conclusive Remarks

The classical paradigm of autoimmune pathogenesis involving specific gene makeup and exposure to environmental triggers has been recently challenged by the addition of a third element, the loss of intestinal barrier function. Genetic predisposition, miscommunication between innate and adaptive immunity, exposure to environmental triggers, and loss of intestinal barrier function secondary to dysfunction of intercellular TJ all seem to be key components in the pathogenesis of autoimmune diseases. Both in CD and T1D gliadin may play a role in causing loss of intestinal barrier function and/or inducing the autoimmune response in genetically predisposed individuals. This new theory implies that once the autoimmune process is activated, it is not auto-perpetuating, but rather can be modulated or even reversed by preventing the continuous interplay between genes and environment. Since TJ dysfunction allows this interaction, new therapeutic strategies aimed at re-establishing the intestinal barrier function offer innovative, unexplored approaches for the treatment of these devastating diseases.

References

The structural components of intercellular tight junctions can be classified as integral membrane proteins (occludin, claudins, and JAM), junctional complex proteins (ZO-1, ZO-2, p130 or ZO-3, 7H6, Symplekin, and cingulin), and cell cytoskeleton structures (microtubules, intermediate filaments and microfilaments).

Figure 1.
Macroscopic arrangement (A) and microscopic composition (B) of intercellular tight junctions.
Figure 2.
Postulated mechanism of action of gluten in T1D pathogenesis. Diet affects the composition of the intestinal microflora. A hydrolyzed casein (gluten-free) diet reduces the number of *Bacteroides* species within the microflora, while the diabetogenic (gluten-containing) diet favors a high titer of *Bacteroides* [1]. Colonization of the gut with an imbalanced microflora in which the *Bacteroides* species is favored over other species, such as *Bifidobacterium* and *Lactobacillus*, activates the zonulin pathway [2]. In parallel, gliadin, a component of the grain protein gluten, binds to the chemokine receptor CXCR3 (expressed on intestinal epithelial cells) and induces a MyD88-dependent activation of the zonulin pathway [3]. A hydrolyzed casein diet prevents activation of the CXCR3-zonulin pathway [4]. Activation of the zonulin pathway leads to increased zonulin release [5]. The released zonulin binds to zonulin receptors on the surface of the intestinal epithelium and causes disassembly of TJs by causing changes in TJ dynamics, including phosphorylation of occludin and ZO-1, changes in occludin-ZO-1 and ZO-1-myosin IB protein–protein interaction, and actin polymerization [6]. The disassembly of TJs leads to the impairment of the barrier function, leading to increased passage of luminal antigens in the lamina propria where they are taken up and processed by mucosal antigen-presenting cells and presented to T cells [7]. The cascade of immune events eventually leads to autoimmune disease [8].
Zonulin signaling

Proposed zonulin intracellular signaling leading to the opening of the intestinal TJs. Zonulin interacts with a specific surface receptor [1] whose distribution within the intestine varies. The protein then activates phospholipase C [2] that hydrolyzes phosphatidyl inositol [3] to release inositol 1,4,5-tris phosphate (PPI-3) and diacylglycerol (DAG) [4]. PKCα is then activated [5], either directly (via DAG) [4] or through the release of intracellular Ca$^{2+}$ (via PPI-3) [4a]. Membrane-associated, activated PKCα [6] catalyzes the phosphorylation of target protein(s), with subsequent polymerization of soluble G-actin in F-actin [7]. This polymerization causes the rearrangement of the filaments of actin and the subsequent displacement of proteins (including ZO-1) from the junctional complex [8]. As a result, intestinal TJs become looser (see freeze-fracture electron microscopy). Once the zonulin signaling is over, the TJs resume their baseline steady state.
